## 1. Introduction

Spatial, temporal, and sectoral completeness of the Climate TRACE emissions inventory is critical to reducing greenhouse gas and pollutant emissions: A complete and bottom-up accounting of emissions provides a full view of when and where emissions *could* be reduced. Furthermore, metadata for these emissions – from the magnitude of emissions-causing activity to the confidence level of estimates – provide insight into *how* emissions can be reduced and how effective those changes might be. However, the raw measurements and inferences performed for each sub-sector may not be complete, meaning that missing values or other minor inconsistencies must be addressed post-hoc. In this document, we describe the suite of imputation techniques we use to ensure every reported source of emissions has estimates for all reported times in the Climate TRACE inventory, and that each of these estimates has associated metadata.

While each subsector’s emissions may be modeled independently, they can all be cast into a sector-agnostic mathematical framework (US EPA, 2024). This enables us to use a common set of interventions to clean the data and impute any missing values, regardless of the sector, location, and gas. These interventions generally fall into three categories of imputation: fully constrained imputation, under-constrained imputation, or over-constrained imputation. In the fully constrained case, the existing information about an emitting source or “asset” is enough to constrain the values of any missing information. In the under-constrained case, only some information is provided, and missing information must either be interpolated from other Climate TRACE data or provided by an external source. Lastly, in the over-constrained case, information may exist for all or some of the emissions and metadata quantities, but some of the values are in contradiction to each other.

In Section 2, we describe the raw Climate TRACE data which may have missing or inconsistent information and then the set of interventions applied to achieve completeness. In Section 3, we detail the outcome of these interventions. Finally, in Sections 4 and 5, we discuss the implications of the interventions and outline future improvements.

## 2. Materials and Methods

### 2.1 Datasets Employed

The primary input dataset was the bottom-up inventory of emissions and metadata for each Climate TRACE asset for a given start and end time and gas as provided by Climate TRACE coalition members for each sector. These inputs came either in a catalog form or in rasterized form. In the rasterized case, we aggregated each quantity to predetermined spatial boundaries, namely the Database of Global Administrative Areas (GADM, 2022) and Global Human Settlement Functional Urban Areas (Schiavina et al 2019), and converted them to a catalog form which was concatenated with the rest of the data set. Table 2 in the Supplemental Materials shows the counts of the number of rows for each sector and gas from these data over all times starting from 2021.

The following metrics are required for each asset for comprehensiveness and comparability. However, depending on the sub-sector, some have all the metrics provided whereas others may have missing (NULL) metrics:

- **Emissions metrics:**
  - Emissions quantity  $E$ : The mass of emissions emitted for a specific gas or pollutant.
  - Activity  $A$ : The amount of sub-sector-specific activity occurring that is producing emissions.
  - Capacity  $C$ : The maximum amount of activity possible for the source.
  - Capacity factor  $\kappa$ : The ratio between activity and capacity. In most cases this is the fractional utilization of the total capacity, but in select cases is a unit-ful quantity that also transforms from capacity to activity units.
  - Emissions factor  $\epsilon$ : The amount of emissions per unit activity for a given gas or pollutant.

- **Robustness metrics:**

- **Confidence:** A categorical confidence score associated with each of the above quantities. It can take values “very low”, “low”, “medium”, “high”, or “very high” indicating the robustness of the associated emissions metric. Each sub-sector may have a different approach to classifying estimates into these confidence categories.
- **Uncertainty:** A numerical value representing the width of uncertainty around each of the provided emissions metrics. This width may be differently defined depending on the sub-sector: It may be e.g. a 1-sigma credible interval or confidence interval, or a range that brackets the possible true value around the emissions metric.

By definition, each Climate TRACE asset has (or must have) the following emissions metrics that must obey the following equation:

$$E = \epsilon A = \epsilon \kappa C. \quad (1)$$

The time-segments (i.e. the windows of time over which the estimates are reported with start and end times) associated with each of the above quantities may be of varying granularity depending on the sub-sector, but all estimates are given on an annual, quarterly, or monthly segment. The equation above also defines our notion of emissions data being fully, under, or over-constrained: Fully constrained means that a missing variable could be solved for by two other known variables in Equation 1. Underconstrained would mean that one or no variables can solve for a missing value, and overconstrained means that the existing variables do not obey Equation 1.

Table 3 in the Supplemental Materials section summarizes the state of input emissions metrics to our imputation procedures. For each of the emissions metric quantities, we report the percentage of entries that were missing. We also report the percentage of over-constrained values by computing fractional differences between the reported activities and emissions and their expected values given the reported capacities times capacity factors and activities times emissions factors, respectively. For the purposes of identifying highly mismatched metrics, we choose to threshold on 0.05 as a fractional difference that constitutes an over-constraint:

$$\frac{|\kappa C - A|}{A} = \frac{\Delta A}{A} > 0.05 \quad (2)$$

$$\frac{|\epsilon A - E|}{E} = \frac{\Delta E}{E} > 0.05 \quad (3)$$

For example, a mining asset with a capacity of 2 tonnes of ore, a capacity factor 0.5, and an activity of 2 tonnes of ore would be identified as overconstrained, because the product of capacity and capacity factor is not within 5% of the reported activity. Note that this 5% threshold is not used within the data processing and is just to illustrate in Table 3 where there are larger rounding errors.

## **2.2 Model Development**

At a high level, we process each Climate TRACE sub-sector's data separately, with the raw asset-level data flowing through a set of sequential interventions, each of which further cleans or imputes the data. Below, we describe the input data, external datasets that are used, and the set of interventions.

### **2.2.1 Emissions metrics**

We examined the raw data submitted by each sector to assess which general interventions may be needed to fill in any missing emissions metrics and ensure adherence to Equation 1. Through this process, we identified a set of common interventions to apply to all sectors by default. If the data from a sector had no missing values or mathematical inconsistencies, it would pass through each intervention step without any change. We describe these interventions below and then summarize the order in which they are applied in Table 1.

#### **2.2.1.1 Fully Constrained Imputation**

The most frequent intervention was for imputation in the fully-constrained case, which we refer to as “NULLtuplication,” because NULL (i.e. missing) values were filled in via multiplication (or division) to satisfy Equation 1. In a NULLtuplication step, first any missing capacity, capacity factor, and then activity values were each solved for using the other two values, if the other two were not missing. For example, if  $A$  was NULL, we would fill it in with  $A = \kappa C$  if  $\kappa$  and  $C$  were not missing. If  $C$  was missing, we filled it with  $A/\kappa$ , and so on. We then performed the analogous operation on the activity, emissions factor and emissions quantity. Finally, we attempted another solve for the capacity and capacity factor in case the activity was solved for via emissions quantity and emissions factor in the previous step.

#### **2.2.1.2 Under-Constrained Imputation**

If a value could not be filled in via NULLtuplication, we imputed it using other times and/or assets for the same sector (and the same gas for emissions factors or quantities). Each time an unconstrained imputation operation was performed, a NULLtuplication step followed

immediately thereafter to ensure that any missing values that were now fully constrained would be solved for. This also prevented introducing over-constrained entries.

A simple but common case was where emissions quantities or emissions factors were missing because they were meant to be zero. Through communication with sector leads, we determined which of these missing values should be zero and collated the list for use in our imputation pipeline. See Table 2 in Supplemental Materials for details.

If an asset had emissions metrics for some time-segments but not others, we first backward filled the missing values in time, and then attempted forward fill any remaining NULLs, thereby always preferring to fill with the most recent data. These backward/forward fills operated on each type of emissions metric independently, in order of emissions factor, capacity factor, capacity, and activity (emissions quantity was filled in automatically by a NULLmultiplication step once activity and emissions factor were calculated).

For assets that were missing some emissions metrics for all reported times and could not be filled in via NULLmultiplication and backward/forward fills, we attempted a “regional” imputation. We filled missing emissions factors and capacity factors with the median of those metrics from assets that had data for the same ISO3 country, sector, and time-segment (and gas for emissions factor). We did the same using mean values for capacity and activity, since capacity and activity quantities add to each other whereas the factors do not. We followed the regional imputation with a global analog for any remaining missing values.

As a final stopgap for remaining missing emissions metrics, we pulled from a hand-curated list of emission factors and if needed set capacity factors to 1. The only case requiring the use of a default emission factor was CO<sub>2</sub> in the coal-mining sector. We used the value of 0.0175 tonnes of CO<sub>2</sub> per tonne of coal extracted, following Table 4-5 of Skone (2018).

### **2.2.1.3 Over-Constrained Imputation**

In some cases, the emissions metrics were over-constrained (>5% relative error in the expected multiplicand). These few over-constrained cases were caused by rounding of some very small raw values. We performed two operations to bring these back into alignment with Equation 1. First, if one or more of the metadata metrics was zero but the emissions quantity was non-zero, we turned those metadata metrics with zeros to NULL values and imputed them with the methods described in the previous sections, e.g. using a regional imputation to fill in NULL values. Then, as a very final step after all imputations, we “forced” consistency with Equation 1 by recomputing all emissions factors and capacity factors. This affected only the few asset entries where rounding of very small values in the input data had broken Equation 1.

#### 2.2.1.4 Summary and Order of Default Imputations

In Table 1, we summarize the default imputations and the order we performed them in. We applied these imputations to all sectors and gases, except CO<sub>2</sub> equivalents, which were re-calculated post-hoc after imputation on the constituent gases as described in Section 2.2.1.6.

**Table 1** Summary and order of default imputations applied to all sectors and gases

	Imputation
1	NULLtiplication
2	Turn zero-valued metadata into NULLs if emissions quantity was non-zero
3	Turn NULL emissions quantities and emissions factors to 0 for assets that are known to have no emissions
4	Backward/forward fill in time by asset
5	Regional imputation
6	Global imputation
7	Fill NULL emissions factors with default values
8	Force capacity factors and emissions factors to obey Equation 1

#### 2.2.1.5 Sector-Specific Imputations

##### 2.2.1.5.1 Cropland Fires

Cropland fire emissions only had reported emissions quantities in rasterized data. We aggregated these emissions to GADM and GHS-FUA regions. So, as a first step before any default imputation, the activities and capacities for these aggregations were set to the area of their respective aggregation regions. The capacity factors and emissions factors were then solved with Equation 1.

##### 2.2.1.5.2 Forestry Sectors

Some time-segments did not have reported data in the forestry sectors (forest-land-degradation, forest-land-clearing, forest-land-fires, shrubgrass-fires, wetland-fires, and removals) from which to do regional and global imputations by time-segment. As such, regional and global fills were

also performed over all time-segments on the emissions factors and capacity factors to bootstrap the existing data to impute other time-segments.

#### **2.2.1.5.3 Mining Sectors**

Copper-mining and bauxite-mining sectors also had some assets that could not be imputed from other assets for the same time period. We therefore used regional and global imputations on emissions factors and capacity factors that used data from all time-segments. Additionally, some small activity and capacity values had been rounded in the input data causing some imputed capacity factors to be larger than one, even though capacity factors were defined to be between zero and one in these sectors. Any imputed capacity factors that exceeded one were set to exactly one and Equation 1 was used to recompute the capacity based on the activity.

#### **2.2.1.5.4 “Other” Sectors**

Several manufacturing sectors were submitted with only emissions quantities and no associated metadata, as described in Moore et al (2024). For each asset in these sectors (other-chemicals, other-metals, other-manufacturing), the activity and capacity were simply defined as “1 factory.” Therefore, the resulting capacity factor was set to 1 in every case, and the emission factor for each gas was the emission quantity per manufacturing facility.

#### **2.2.1.6 CO<sub>2</sub> Equivalents**

CO<sub>2</sub>-equivalent global warming potentials for 20-year and 100-year periods are provided in the Climate TRACE data as well. While these equivalents for a given time-segment and asset may have been present in the input data, we recomputed these from scratch after all imputations had been performed on the CO<sub>2</sub> equivalent constituent gases (CO<sub>2</sub>, N<sub>2</sub>O, CH<sub>4</sub>). For CH<sub>4</sub>, we use CO<sub>2</sub>-equivalent global warming potentials of 81.2 and 27.9 for 20-year and 100-year periods, respectively. For N<sub>2</sub>O, we use 273 for both 20-year and 100-year periods.

#### **2.2.1.7 Spatio-Temporal (Dis)aggregation of Estimates**

In order for the Climate TRACE inventory to have uniform resolution in time, emissions metrics were resampled to a common time grid as described in Raniga et al (2024). For emissions aggregated to specific spatial regions such as GADM or GHS-FUA boundaries, the metadata were aggregated as well by aggregating the activity and capacity and then solving for an average capacity factor and emissions factor via Equation 1. These spatio-temporal operations were performed after missing input data were imputed with the methods described in the previous sections.

### 2.2.2 Confidence

We took a similar approach to imputing missing confidences as we did with emissions metrics. An ordered set of operations were performed to fill out confidence scores for every asset, gas, and time. First, we performed the equivalent of a NULLtiplication operation but on confidences. If confidences existed for two emissions metrics, but a confidence was missing for a third one that could be constrained by the first two, we filled the missing confidence with the lower confidence of the two existing estimates. For example, if an emissions quantity was missing a confidence, it was filled with the lower of the confidences of the emissions factor and activity. A similar operation was performed for CO<sub>2</sub> equivalent confidences: the lower of the confidences of the constituent gases was used for imputation.

In cases where missing confidences were unconstrained by other confidence values, we filled them with the lowest confidence for that sector, gas, and value. Next, there were some cases where confidences were missing for emissions factors and emissions quantities because that gas was not expected to be emitted in that sector. In those cases, we set the confidence to “very high,” with the corresponding emissions metrics being zero. Note that many of these very high estimates were downgraded to “high” from temporal downscaling described below. The final missing-confidence imputation operation was to fill any confidences that were still NULL with “very low.”

After the NULL confidences were filled, we re-sampled all the confidences to the time granularity of the final emissions metric data (monthly). Any confidences that were not already originally at monthly (and therefore were coarser estimates in time) were downgraded by one confidence level indicating the uncertainty associated with temporal disaggregation. Estimates for any times that were missing coverage in the input data entirely were assigned “very low” confidence.

### 2.2.3 Uncertainty

A single, generic approach was taken to impute missing uncertainty information and standardize the information to the common temporal granularity, regardless of the sector and gas. Uncertainty values provided in the input data from coalition members were roughly treated as the standard deviation of a Gaussian distribution around the corresponding emissions metric estimate. The emissions metrics were treated as independent variables for simplicity, although Equation 1 does imply correlations among different quantities (Note that large uncertainties compared to their associated emissions metrics were not interpreted to imply negative emissions, and instead interpreted as a distribution that truncated at zero).

For assets that had uncertainties for some times but not others, we imputed each asset’s missing uncertainties using the median uncertainties for each emissions metric for that asset over all times. If uncertainties existed for some but not all assets in a given sector, the median relative variance of all assets/times for a given gas was applied to any missing assets/times. If uncertainties did not exist for a given sector, the median relative standard deviation reported over all assets and all times for a given gas was applied to the missing values.

To resample the provided uncertainties to the common temporal granularity, we first compared the emissions metrics between the (cleaned and imputed) data with and without monthly resampling. If the emissions metrics were the same, the provided uncertainty was left unchanged. If instead a metric changed by some factor  $f$  through the monthly resampling, the variance (square of the standard deviation) was scaled by  $f$  as well. This operation preserved the input variance as being the sum of variances of estimates at finer temporal granularities.

If no uncertainty value  $\sigma_{orig}$  was provided in the input data for emissions quantity, activity, or capacity, the imputed uncertainty  $\sigma_{imp}$  was calculated using

$$\sigma_{imp}^2 / M_{imp} = \text{median}(\sigma_{orig}^2 / M_{orig}), \quad (4)$$

where  $M_{imp}$  and  $M_{orig}$  were the imputed and original emissions metrics. The median was taken over either all times for the same asset, or if that data was not available, all assets in the sector. Emissions-factor and capacity-factor uncertainties were imputed similarly, with one key difference: if uncertainties did not exist in the input data, we took the smallest of the following possible values:

- Equation 4 with the median over all times for a given asset and gas
- Equation 4 with the median over all assets for a given sector and gas
- The larger of:
  - the standard deviation of  $M_{orig}$  in that sector, gas, and country, or
  - 5% of  $M_{imp}$
- 50% of  $M_{imp}$

This scheme automatically probed cases where a very specific emissions factor or capacity factor was used in a sector and country, suggesting it should have low (but not lower than 5%) uncertainty, while also controlling the uncertainty from becoming excessively large.

If the requisite data for  $\sigma_{orig}$  or  $M_{orig}$  did not exist for any of the above calculations, a blanket 50% uncertainty was applied. A 50% uncertainty was also applied to all metrics in the scraped-asset sectors described in Moore et al (2024), but capacity factor was given an uncertainty of 0.1. Capacity factor for lime, however, was kept as a 50% uncertainty. The choices herein were made so that uncertainties could be simply imputed across all sectors using the available information, while not introducing uncertainties that were unreasonably small or large.

### 3. Results

After performing the imputations from Section 2 on the input data, all missing and over-constrained values are eliminated. Table 2 shows the effect of our imputations on global emissions quantities. Only sectors where the absolute value of the percent change is at least 0.1 are shown. The mining sectors showed the largest increase from imputations because many assets' emissions quantities were missing in that sector. All other sectors' totals for 2023 changed less than 10%. The apparent negative changes shown in Table 2 are artifacts from our use of different global warming potentials as described in Section 2.2.1.6, not the underlying constituent gases. While imputing missing values had a small effect on emissions quantities overall, it nonetheless produced a complete dataset, giving users of the data an estimate for every quantity for each asset and time reported.

**Table 2** Absolute difference and percentage change of total 2023 CO<sub>2</sub> equivalent (100 year global warming potential) emissions in millions of tonnes (Mt) for reported assets between the input data and data after imputation

## 4. Discussion

The imputations we perform to achieve completeness of the input data make only a modest increase to total emissions in the inventory. However, a considerable number of metadata are imputed as shown in Tables 3 and 5. Many of the missing emissions metrics are immediately filled through NULLtiplication or through setting missing values to zero which are known to be a-priori. These imputations will enable stakeholders to easily investigate future changes in activity and emissions factors effected by pollution control measures that mitigate asset-level emissions and achieve climate goals.

In terms of the confidences, many emissions quantity and emissions factor confidences are filled with “very high” because those values are known to be zero. Otherwise, most missing confidences are filled with “very low” to be conservative. Future work could refine these confidences further.

The uncertainty widths we imputed and re-sampled are a starting point for assessing the numerical uncertainty of Climate TRACE asset data and provide some numerical estimate to accompany confidences. However, we note that the input uncertainties may not be comparable between sectors and the full multivariate distributions of emissions metrics are not modeled here. Therefore, future work is needed to provide more robust uncertainty metrics.

Temporal disaggregation of both the metadata and the emissions estimates makes the Climate TRACE inventory both complete and also high-resolution in time. The confidences and uncertainties reflect the extra operations performed on the data for imputation and standardization.

Overall, the scheme outlined in this methodology has the advantage of being simple and sector-agnostic, making any changes to the data transparent and reproducible. However, the

sequential nature of the imputations does not account for correlations among different variables. We may explore multivariate techniques in future work.

## 5. Conclusion

In sum, we standardized the Climate TRACE dataset as reported directly from coalition members by filling missing data and re-sampling to a common monthly time resolution. We used a set of simple, sequential operations to achieve completeness of the data over time and over assets. The effect on total emissions quantities was little to none in most sectors.

**Permissions and Use:** All Climate TRACE data is freely available under the Creative Commons Attribution 4.0 International Public License, unless otherwise noted below.

**Data citation format:** Moore, D., Doctor, Z, Raniga, K., Lewis, C., Sridhar, L., Thomas, P., Saraswat, I., Collins, G., Nellis, A., Brown, N., Pekala, M., Rokisky, J., Reilly, E., Hughes, M. and McCormick, G. (2024). *Completeness of Bottom-up Emissions Estimates and Associated Metadata*. WattTime and Johns Hopkins University Applied Physics Laboratory, USA, Climate TRACE Emissions Inventory. <https://climatetrace.org> [Accessed date]

**Geographic boundaries and names (iso3\_country data attribute):** The depiction and use of boundaries, geographic names and related data shown on maps and included in lists, tables, documents, and databases on Climate TRACE are generated from the Global Administrative Areas (GADM) project (Version 4.1 released on 16 July 2022) along with their corresponding ISO3 codes, and with the following adaptations:

- HKG (China, Hong Kong Special Administrative Region) and MAC (China, Macao Special Administrative Region) are reported at GADM level 0 (country/national);
- Kosovo has been assigned the ISO3 code ‘XKX’;
- XCA (Caspian Sea) has been removed from GADM level 0 and the area assigned to countries based on the extent of their territorial waters;
- XAD (Akrotiri and Dhekelia), XCL (Clipperton Island), XPI (Paracel Islands) and XSP (Spratly Islands) are not included in the Climate TRACE dataset;
- ZNC name changed to ‘Turkish Republic of Northern Cyprus’ at GADM level 0;
- The borders between India, Pakistan and China have been assigned to these countries based on GADM codes Z01 to Z09.

The above usage is not warranted to be error free and does not imply the expression of any opinion whatsoever on the part of Climate TRACE Coalition and its partners concerning the legal status of any country, area or territory or of its authorities, or concerning the delimitation of its borders.

**Disclaimer:** The emissions provided for this sector are our current best estimates of emissions, and we are committed to continually increasing the accuracy of the models on all levels. Please review our terms of use and the sector-specific methodology documentation before using the data. If you identify an error or would like to participate in our data validation process, please [contact us](#).
